Abstract

Perceived similarity between images is an achievement of complex processes of vision, of cognitions and emotions. It may be influenced by the context and the content of images, semantic associations and the intention of the observer, to name a few. But simple, low-level features are used successfully to compare images. For instance, color histograms are used in content-based image retrieval (CBIR) systems and frequently result in perceptual and often semantically similar images.

Our goal was to create an image indexing system based on some of the known properties of the early stages of human vision. A color space (DKL) found to underlie human vision (Krauskopf et al., 1982) was used to create color histograms. In the DKL space color bins, independent of luminance, were created using a logarithmic spacing which reflects the granularity of higher order color perception. The frequency and the average luminance level of the color bins were stored in a chromaticity and a luminance histogram respectively. A spatial index encodes – in analogy to transformation in the visual cortex – information about orientation and spatial frequencies of the images. The information was extracted using a 2-dimensional discrete Fourier transformation (DFT). The Fourier spectrum was divided into logarithmicradial bins representing contrasts of distinct orientation and spatial frequency ranges.

In three experiments we quantitatively measured the relationship between the similarity order induced by the indices (and index combinations) and perceived similarity in a 2-alternative forced-choice (2AFC) design. For the experiments we used a large, commercially available database (Corel Corp., 1990) of 60,000 digitized photographs. In contrast to previous evaluation approaches we measured the relationship not only for the few best matching images but for relatively distinct images, too.

Results show that the similarity rank orders induced by the indices are strongly correlated with the human judgments (r > .95) and predict perceived similarity even for quite distinct images. The highest index concordance was obtained using the chromaticity index. Combining the three information sources improved the correspondence with the observers by 9%.

Therefore, chromaticity, luminance and the spatial features contribute to the perceived similarity of images and can be used to predict the judgments of the observers for very similar and for relatively distinct images, too.

1 Introduction

The goal of image indexing systems is to find a set of images that is similar to the target image the user is looking for. Depending on the intention of the user, similarity may be defined by objects, configuration, illumination, camera position or zoom, or semantic perception by the user, or any combination of the above. Preferably, computer vision algorithms should extract all the relevant features from the image in the same way a human observer would do. But that is far beyond our current knowledge of human vision, cognition and emotion.

Most of the current algorithms are quite successful in using lowlevel features of the images, as this quite frequently results in semantically related images. Color, in particular, has proven to be very effective for the calculation of image similarity, since an object's color is independent of viewing position or viewing distance. The most prominent color statistics are histograms with equally sized bins in RGB or HSI color space. In HSI space the luminance (intensity) axis is often ignored since it is argued that the overall brightness of an image is irrelevant with respect to image similarity and hence luminance independent indices should be more robust with respect to different illumination conditions. Other color statistics include correlation or covariance coefficients encoding spatial information about the color distribution (e.g. Huang et al., 1999, Stricker and Dimai, 1997). Features such as texture and shape are other subjects of current research (e.g. Flickner et al., 1995).

All these approaches are based on physical, low-level features. But in the end the similarity of a given image with a target image will always be judged by a human observer. Therefore, our goal was to construct indices which are based on some of the known properties of the early levels of the human vision system. Furthermore, we evaluated the resulting image metric by comparing it with measurements of perceived image similarity.

As the first step of seeing, light is absorbed and converted into neu-

ral signals by the three different classes of cone photoreceptors in the retina. The details of the absorption spectra of the cones were well studied in the past and are known quite precisely by now. While these cones are often called red-, green- and blue-cones, they all do absorb light over a wide range of the visible spectrum. Most notably, they do not have much to do with the RGB-triplets of modern image sensors. There is no simple transformation converting between the two, and any such conversion process requires careful calibration of the image acquisition device (Wandell, 1993).

Still at the level of the retina, the signals from the cones get transformed by a complex network of retinal cells (Wässle and Boycott, 1991) into color opponent signals. Electrical recordings from single neurons in the retina and the later geniculate nucleus have shown three different classes of neurons. A "luminance-type" neuron simply takes the sum of the outputs from all three cone classes. "Red-green" opponent neurons take the difference between the red- and the green-cone signal. "Blue-yellow" opponent neurons take the difference between the bluecone signal and the sum of the red- and green-cone signal. Incidentally or not, this basically results in a principal components analysis of the cone signals (Buchsbaum and Gottschalk, 1983) and thus removes any correlation between the signal channels, resulting in nearly optimal information transmission from the eye to the brain.

In the visual cortex, spatial information is extracted from these signals using an array of linear and non-linear filters tuned to spatial frequency and orientation (Hubel and Wiesel, 1998). The tuning characteristics of these filters seem to be highly optimized for viewing our typical visual environment (Field, 1987). The efficiency of these spatial filters was modeled by Watson (1987). He transformed the grayscale image using discrete Fourier transformation (DFT) and applied a filter to the coefficient matrix with the same orientation and bandwidth properties found in early spatial vision. In a psychophysical experiment he found that a reconstructed image is indistinguishable from the original at a code size of 1 bit/pixel. We tried to use these established coding principles of the human visual system to construct image histograms optimized to these characteristics. The color space (DKL) proposed by Derrington et al. (1984) in the CGL of macaques was also found to underlie human color vision. Krauskopf et al. (1982) showed that the increase of thresholds for detecting colors after adaptation to isoluminant color changes is independent along the color-opponent axes.

We used that color-opponent space to create two color indices using the method of Krauskopf and Gegenfurtner (1992). A first index encodes only chromaticity and is therefore luminance independent. The second index encodes the mean luminance of the color tones. For the color bins we did not use a equidistant spacing, the size of the bins reflects the granularity of higher order color perception e.g. for saturated colors the resolution for hue is much finer than it is for unsaturated colors while the resolution of saturation decreases, in agreement with Weber's Law.

To extract the spatial information we used the luminance dimension, which is, in the DKL color space, orthogonal to the color-opponent subspace used for the color indices. For each image the Fourier power coefficients were calculated using DFT. The 2-dimensional power spectrum was further segmented into bins representing spatial contrasts of distinct orientation and frequency ranges. The resolution of the Fourier index is a function of frequency and orientation, representing orientation of high frequency contrasts more exactly than of lower frequencies.

The second major aspect of our system is its evaluation. Most of the earlier search systems were evaluated informally only. The prevalent method is to have the experimenter decide which images found by the search algorithm are similar to the query image. As Cox et al. (2000) criticize the results obtained by such methods are highly dependent on the strictness of the similarity criteria the observers use, the homogeneity of the images in the database and the number of images displayed.

We evaluated the resulting color indexing system based on percep-

tion (CISBOP) by comparing the similarity judgments made by the algorithm to ratings made by human observers. Unlike Rogowitz et al. (1998) who calculated a similarity metric for a set of 96 images with multidimensional scaling technique, we tried to measure similarity directly. By looking at the degree with which the algorithm correlates with the observers, we can estimate which feature (index) contributes to the human observers' judgments.

For measuring image similarity Cox et al. (2000) propose three methods. In the 'absolute-similarity' configuration a target image is compared with a test image and subject must judge the degree of similarity between the two images. In the 'relative-similarity' configuration the target image is shown with two test images below. The subject could indicate by low values on a 5-point scale that the left image is more similar to the target image than the right image and by high values that the right image is more similar. In the '2-alternatives forcedchoice' (2AFC) configuration the user could indicate only which of the two images he finds more similar to the target image.

We chose the 2AFC configuration for the evaluation of the indices. The advantage of the 2AFC is that the subjects do not need to calibrate their scales of similarity judgments. However Papathomas et al. (1998) report that the 2AFC choices are strongly correlated with the other choices in the other configurations.

In three experiments we measured the relationship between the perceived similarity judgments and the computed similarity distance over a broad range of similarity. The similarity of images was varied from quite similar best matches to relatively distinct for images with rank 2000 in the result list.

In a first experiment we investigated the influence of the degree of similarity between the test images on the similarity judgments. In the second experiment the three indices were compared to each other to determine the contribution of each index and in the third experiment the indices where combined iteratively to measure the improvement of user prediction when spatial or luminance information considered.

2 Similarity of Images

Judging the similarity of images could be a difficult attempt. Images can be 2-dimensional representation of anything: objects, animals or people, from detailed close-ups to blurred scenes. Furthermore, if two images are compared it largely depends on the context whether they are regarded as related. For example, considering two portraits of a woman and a man: these could be judged to be very similar if the images in a database usually show landscapes or architecture. In database of faces, depending on the persons photographed, they may not appear to have anything in common. Domain knowledge, the intention of the observer, the kind of objects photographed, all could influence the perceived similarity. Therefore, an empirical approach to perceived similarity of images is difficult.

Similarity judgments are complex achievements of the human vision system, of cognitions and emotions. The results obtained by the MDS analysis for small image sets could not be generalized and there currently exists no psychological theory of image similarity. Nevertheless, it would be useful to have some measure to estimate similarity, even if it is deficient.

The major applications of similarity measures are image retrieval systems searching for similar images in databases. Astonishing similar and often semantically related images could be found by comparing the images by their low-level features. The similarity information can be used to predict the judgments of the users. The PicHunter system (Cox et al., 2000) uses such a model. It shows a set of images to the user who then indicates which are related to his target image. Based on pictorial features and the Bayesian user model the algorithm integrates the current with the previous information and selects a new set of images. In a database of 4522 images single target images can be found in about 35 iterations using simple pictorial features only.

If low-level features can be used to find similar images then these features must be related to the perceived similarity, either because the concepts of similarity is based on the low-level features or because there exists a correlation in images, e.g. between the color and the meaning of objects. In both cases the relationship between the perceived low-level features and the judged similarity would be of high importance.

With the experiments we could not bridge the "semantic gap" (Smeulders et al., 2000). But we propose a method how it could be measured.

3 Related Work

There currently exists a great variety of content-based image retrieval (CBIR) approaches. In currently published review Smeulders et al. (2000) cite more than two hundred references, the majority published in the second half of the last decade. The objective of most studies is to develop suitable and robust feature sets that could be used to compare images.

Since the article of Swain and Ballard (1991) color histograms are standard components for image indexing systems and have been proven to frequently retrieve a high proportion of the related images in a database. In addition to simple, low-level features complex features, for example wavelet transformations, are applied with great success in CBIR systems, too. Which features are the best suitable in which contexts is still uncertain. Smeulders et al. (2000) stated that in their reviewed publication "fair comparisons of methods under similar circumstances have been virtually absent".

3.1 Analysis of Human Judgments

For small sets of images the major dimensions of the similarity judgments were investigated using multidimensional scaling techniques (MDS). Rogowitz et al. (1998) used a set of 96 images that were printed on cardboard. The subjects judged the similarity of image pairs on a rating scale. Based on the MDS analysis of the similarity comparisons, the images were arranged in a 2-dimensional space. The authors describe the major dimensions as natural vs. man-made and human vs. animal-like. Its interesting these dimensions are correlated with color.

An even narrower image repertoire was used by Mojsilociv et al. (2000). They let the subjects compare 20 images of colorful textures taken from an interior design catalog. In addition to MDS they analyzed the observers' comparisons in a hierarchical cluster analysis. With both techniques they found similar grouping criteria: overall color, color purity, regularity and placement, and directionality.

3.2 Evaluation

Image indexing techniques are usually evaluated by precision measures stating the average proportion of similar images in the results set. Papathomas et al. (1998) criticize the usage of the criterion "similar" because it could be understood in various ways by different observers. Moreover, the precision measure depends on the proportion of similar images in the database. They suggest using an identical-targetcriterion ("target testing", Cox et al. (2000)) instead, or to compare the search length until a similar image is found against search lengths if the user's feedback is ignored (random browsing).

Similarity judgments can be given using either an absolute or relative scale. In their first experiment Papathomas et al. (1998) compared absolute image comparisons to similarity judgments given on a relative scale. They found a high correlation between the frequency of preferring an image in the 2AFC condition and the similarity ratings given on a scale from -2 to 2. This relationship follows the form of a psychometric function.

3.3 Color and Luminance

Color information is a major aspect of image similarity. Our goal was to construct color histograms based on some of the knowledge of early color processing. In CBIR systems color histograms are usually created in the RGB space using either Cartesian (RGB) or cylindrical (HSI) coordinates.

Psychophysical uniform color spaces were used to compare single color values of images, for example the average or the most dominant colors (Mojsilociv et al., 2000). Such indices may be only appropriate for very colorful image with one or a few dominant colors. For databases with objects photographed under different illuminations, color histogram performance can be improved if luminance or illumination invariant color spaces are used (Funt and Finlayson (1995), Gevers and Smeulders (1996), Alferez and Wang (1999)).

3.4 Spatial indexing

To include spatial information, extensions to color histograms were suggested. For instance, Stricker and Dimai (1997) constructed five histograms for fixed overlapping image regions. Huang et al. (1999) used the correlation between pixel colors at different distances for indexing (color correlogram).

Besides the new color-spatial histograms genuine spatial features have been proposed for image index. They include texture features (e.g. Liu and Picard (1996)) and 2-dimensional decomposition techniques such as wavelets (e.g. Wang et al. (1997), Liang and Kuo (1999)). Many texture and wavelet features contain orientation and spatial frequency information and are therefore related to the Fourier spectrum. Second order statistics such as periodicity corresponds to the spatial frequency while directionality is related to the orientation of the Fourier basis functions.

Orientation and frequency information are often analyzed using Gabor filters. Being a convolution of a sine grating and a Gauss function they can be used for a local contrast analysis. The resulting coefficients encode – like the 2-dimensional DFT – orientation and frequency. Gabor filters were used by Itti et al. (1998) in their computational model for rapid scene analysis. The visual attention model, inspired by the architecture of the early visual system, consists of maps encoding coloropponent, center-surround and Gabor features of the image. The distinction between chromaticity, luminance and spatial features is similar to the one we used. The model computes the color and spatial features for an image and then selects the focus of attention by a winnertakes-all strategy. Itti et al. report that the model is robust to the introduction of white or colored noise and that for several pop-out tasks human performance could be reproduced.

Manjunath and Ma (1996) used Gabor wavelet features for texture analysis. Comparing the Gabor wavelet approach with other wavelet transformations, they found retrieval performance using Gabor transformation to be better or at least comparable to the other approaches.

4 Color and Spatial Indexing

The aim of image indices is to create metrics to estimate the similarity of images. Such a metric should ideally correspond to the users' perception of similarity. The idea of our image indexing system based on perception (IISBOP) was to use some the the established coding principals of human vision to compare images.

For each image the distribution of the features hue, luminance and spatial frequencies were determined. These distributions were summarized into three histograms (feature vectors). The similarity between two images were then defined as the distance between the feature vectors. In contrast to previous approaches, we normalized the distance values with regard to the mean and standard deviation of the distribution of similarity distances. The normalization transformation is computed on a per-image basis and leads to index weights that reflect the saliency of the corresponding features.

The main focus our research, besides evaluation, was the first step in similarity metric creation, the modeling of appropriate image features. We used the DKL color space (Derrington et al., 1984) that was found to underlie primate color vision for this purpose. The chromaticity and the luminance information was stored in two separate indices, the information about the Fourier energy distribution in a third histogram.

4.1 Color Transformation

It was mentioned in the introduction that there is no simple transformation to convert RGB-triplets into human cone photoreceptor excitations. But these receptor excitations are necessary to calculate the DKL cone-opponent coordinates for these stimuli. We circumvented this problem by using the photoreceptor excitations resulting from the display of the images on a standardized and calibrated display monitor (Sony GDM-F500). Since our observers made their judgments looking

Figure 1: Color distribution in the DKL space. a) The color distribution of the image with the hats in the bottom left plotted with respect to the coordinates at the color-opponent axes in DKL color space. When multiple pixels had the same position, luminance was averaged. b) Subdivision of the chromaticity subspace of DKL color space into 127 logarithmic-radial color bins used for the color indices.

at the images displayed on that monitor, it is correct to use these excitations as the basis for the similarity metric. The transformation function between the RGB channels the DKL color space was determined using a method of Krauskopf and Gegenfurtner (1992).

The resulting color distribution of an image in the color-opponent space could be visualized by plotting the pixels of the image with respect to their coordinates on the red-green and yellow-blue axis (Fig. 1a). In the chart the pixels of the differently colored hats fall into separate radial sections.

The Cartesian color-opponent coordinates can be transformed into the polar coordinates hue and saturation. In the chart hue is the color angle ($hue = \arg(rg + i \cdot yb)$), saturation is the distance from the neutral gray ($sat = |rg + i \cdot yb|$). The cylindrical hue-saturation coordinates were then used to define the histogram bins.

4.2 Chromaticity and Luminance Index

To create the color histograms the chromaticity plane was subdivided into logarithmic-radial segments (Fig. 1b). The resolution for saturation of these bins decreases with increasing saturation. Six different rings were used to discriminate saturation; the remaining unsaturated color tones in the center were summarized into a single, gray bin. The ring a color tone belongs to can be calculated using the logarithm of the saturation ($r = \lfloor -\log_2 sat \rfloor$). For hue the histogram resolution is lowest for unsaturated, gray colors and doubles with increasing saturation ($n_r = 2 \lfloor 6-r \rfloor$). This yields to 127 bins, 64 bins for the most saturated colors.

Furthermore, color values exceeding 95% or falling below 5% of the possible luminance range of RGB space were classified as white and black. This is essential since the hue resolution of RGB for very dark and very bright colors is limited.

To calculate the two color indices the color distributions of the images were mapped into these 129 bins. For each image two vectors were stored: the frequency of the color tones f and the average luminance level of the pixels in each bin l. If a bin was empty the luminance level was set to zero.

$$f_{bin} = \frac{|pixels|bin|}{|pixels|}$$

$$l_{bin} = \begin{cases} \frac{\sum lum|bin}{|pixels|bin|}, & \text{if } f_{bin} \neq 0\\ 0, & \text{if } f_{bin} = 0 \end{cases}$$

Figure 2a shows the frequency of the color bins for the images with the hats. The brightness of the segments in the chart is linear to their frequency. The most frequent segment is white. In Figure 2b the color tones belonging to each color bin were plotted with the average luminance of that bin giving an impression of the information stored in the luminance vector.

Figure 2: Color histograms. a) Frequency of the color bins for the image with the hats (Fig. 1a). The brightness of the bins is proportional to their frequency in the image. The most frequent bin is white. b) Mean luminance in the color bins for the image with the hats. The color tones belonging to each color bin are plotted with the average luminance level of that bin.

4.3 Fourier Index

To determine the proportion of different orientations and contrasts of different frequencies we used the 2-dimensional discrete Fourier transformation (DFT) to decompose the images. For the decomposition the luminance dimension of the DKL space was used.

In contrast to the local Gabor transformation, the 2-dimensional discrete Fourier transformation is a global decomposition determining the amplitude for a set of 2-dimensional sine waves so that the image could be reconstructed as a linear combination of these basis functions. Each basis function could be characterized by a complex parameter. The polar coordinates of this Fourier parameter are the orientation and spatial frequency of the 2-dimensional sine waves. The DFT calculates for each parameter a complex coefficient storing the amplitude and the phase of the corresponding 2-dimensional sine waves. The image then could be reconstructed as a linear combination of this basis function.

The squared coefficient – the energy – respectively its distribution, the Fourier spectrum was used to construct the spatial index. Because the grayscale values of the transformed images are 1-dimensional the resulting Fourier spectrum is symmetric and for the index creation only the upper half of the spectrum was used.

Since even the fast Fourier transformation (FFT) is computational intensive, the 768x512 sized images were rescaled to 96x64 thumbnails prior to processing using bilinear approximation. The thumbnails were projected into the DKL space. The luminance dimension was then used for the DFT. To correct for artifacts that arise from the rectangular form of the images, a circular mask was convoluted with the grayscale thumbnails prior to Fourier transformation. This further reduces the image size to 64x64 pixels and results in a more even distribution of the energy along orientation dimension because it removes the artifacts resulting from the image edges. But orthogonal components are still most frequent because many images contain objects with vertical or horizontal orientations. The resulting 64x64 Fourier spectrum was divided into radiallogarithmic bins analogous to the chromaticity segments. The index contains 126 bins. Each segment represents contrasts of distinct orientation and frequency ranges. The bins at the origin correspond to contrasts with very low or zero frequency and store the mean luminance of the image. Because we wanted to construct a luminance independent spatial index we did not used these bins for searching; they were excluded by a filter prior to searching.

Figure 3: Fourier index for the image with the hats (Fig. 1a). Spatial frequency increases from the center to the edge of the chart. The central bins containing average luminance information were removed. The brightness of a bin is proportional to the logarithm of the average energy within the bin. The segment with the highest energy is white.

4.4 Distance metrics

To find similar images for a given query image it is necessary to compare the index vectors. Most indexing systems interpret the indices as points in an Euclidian space and use the Euclidian norm to define the distance between two images. We used it for comparing the luminance and the Fourier index.

For the chromaticity frequency index the more intuitive intersection norm was used. It defines the similarity between two images by the sum of the minimum of the corresponding bin frequencies $(s_{is} = \sum_{i=1}^{n} \min(x_i, y_i))$. The value can be interpreted as the proportion the two color distributions share. A value of e.g. 0.75 means that for 75% of the pixels in one image there exist pixels in the other image which fall into corresponding color bins. Figure 4 shows the percentage of color concordance for a sample query using the chromaticity index.

For very similar images the intersection norm yields to a value near one because the sum over the bins of the chromaticity histogram is one. Images that do not share a single color bin are considered completely dissimilar. The similarity value would be zero. To use the intersection norm as a distance measure the similarity value must be negated. The transformation $d_{is} = 1 - s_{is}$ was used.

Figure 4: Sample query results comparing images using the chromaticity histogram and the intersection norm. The number below the images shows the percentage of pixels the images shares with the query image at the top left. The query images shares with itself 100% of the color distribution.

4.5 Cue Combination

To combine the indices it is necessary to normalize the different distance functions. This is not only a consequence of using two different distance functions. Even if different indices are combined using the same distance function normalization is necessary because the variances of the indices are quite different.

We used the z-transformation to normalize the distance values. The use of z-transformation seems reasonable inasmuch as the distance distributions we inspected manually show the form for a skewed Gauss density function (Fig. 5). The parameters of the z-transformation are estimated before each query. For this purpose a set of 1000 random images R is selected. The mean and the standard deviation of the distribution of distances between the query image and the 1000 random images is then estimated ($z_d = \frac{d-\bar{d}}{\hat{\sigma}_d}$).

It is necessary to estimate the parameters for each query image again because the (query) images differ in their mean distances to all images and in the variance of the distance distribution (Fig. 5a and b). These values can be used to characterize the image. If $\bar{d}_s(q, I)$ is great and $\sigma_s(q, I)$ is small then the image q would be quite distinct regarding the similarity metric s used for comparisons. If an image is compared simultaneous with multiple indices then the means and standard deviations characterize the importance of the different features for the comparison with the image database. The distance of an image to itself is zero per definition. Thus the z-value of an image to itself is the (negative) distance between the mean of the database in terms of the standard deviation. If the image is quite distinct from the images in the database then the absolute z-distance would be great.

The distance values of the different indices could then be combinend by averaging the z-values. The z-transformation – calculated for each index separately – therefore ranks the indices in terms of their salience. The indices that are more characteristic for an image are automatically weighted higher than these indices were the images are

Figure 5: Histograms of distance values from two randomly choosen image to a set of 1000 randomly selected images using chromaticity histogram and intersection norm. The distance distributions have different means that will result in different z-values (see text).

alike.

$$z_{S}(q,i) = \frac{1}{|S|} \sum_{s \in S} \frac{d_{s}(q,i) - \bar{d}_{s}(q,I)}{\sigma_{s}(q,I)}$$

Figure 6: Sample query results for a combined search using ztransformation. Below each image the average of the z-values of the chromaticity, the luminance and the Fourier histogram distances is shown.

5 Implementation

The algorithms were implemented into a Java framework. It consists of five modules: database, features, feature combination, filters, a graphical user interface (GUI) and communication protocols. The image database module is URL based and can be used to address either image files or images on http or ftp servers. For a query the different indices can be selected and combined with filters (e.g. removal of DC components in the Fourier spectrum) and one of the two distance metrics (Fig. 7).

Figure 7: Screenshot of the client program running in an internet browser. The database consists of images taken from the web.

The program can be run either as a standalone program or as a client-server combination. The clients can be run as applets in internet browsers which handle the local query definitions and store the query results. The Java remote method invocation protocol (RMI) is used for client-server communication. The server receives the hierarchical query definitions, searches the feature database for images and returns the results and the image URLs to the clients. The images are retrieved by the client applets from the server or the web.

The process of feature creation is script-based. For the 2dimensional discrete Fourier transformation and the bilinear rescaling we used the 'hips' image software package (Landy et al., 1984).

The performance of the program depends on the speed of the computer and the implementation of the Java virtual machine. For the database of 60,000 images used in the experiments it took between one and two seconds to find the best 100 matches for a given image on a 750 MHz Pentium-III based computer running the standard Java implementation of Linux. When all three indices were combined a query was processed in less than five seconds. It should be noted that we only used a linear search strategy not taking advantage of possible bounding assumptions and tree-based data structures. The search could be further speeded up by reducing the number of bins using primary component analysis (PCA).

6 Psychophysical Evaluation

The purpose of the psychophysical experiments was to measure the relationship between the similarity norms created by the indices and the perceived similarity. The similarity between two images was interpreted as a probabilistic function and was measured in a two-alternative-forced-choice (2AFC) design. The correspondence between the similarity computations and the judged similarity was measured for the three indices and three index combinations. In contrast to previous evaluation strategies histogram-based similarity was not only evaluated for a few best matches but for relatively distinct images too.

6.1 Measuring Similarity

For precision/recall evaluation methods similarity is implicitly defined by the judgments of the experimenter. It can be written as a function defining which images are relevant or similar for each query image:

$$a: I \times I \to \{0, 1\}$$

The precision of a result list D of the m best matching images (images having a rank below than or equal to m) can then be simply defined:

$$precision = \frac{1}{m} \sum_{i \in D} a(i)$$

In contrast, we here define the similarity between two images as a probabilistic function:

$$p: I \times I \to [0,1]$$

The perceived similarity can be measured using either an absolute or relative scale. Both methods are highly correlated; the relationship between both measures follows the form of a psychometric function (Papathomas et al., 1998). In the relative case the user indicates the degree of similarity between the query image and the test image on a

Figure 8: 2AFC display used in the experiments. At the top the query image is show, below are two test images (target and distractor positions were randomized).

rating scale. This requires the users to adjust their scale to the content of the database prior to the experiment, e.g. by seeing a list of random images. This may increase the standard error of evaluation measurements. A more objective method is the two-alternative forced-choice configuration (2AFC).

We used a configuration with three images: the query image at the top together with two test images below (Fig. 8). The task of the user was to compare the similarity of the test images with the query image and to select that image that is more similar. We defined the (probabilistic) similarity between the query image and a test image p(q, i) by the probability of preferring the image p(i).

We were interested in comparing the judged image similarity p(q, i) with the similarity order of the indices. In the forced choice configuration the rate of preferring an image is dependent on the degree of similarity between the two alternatives. With the exception of experiment one we kept the similarity of one image, the distractor image, constant. The similarity of the other image, the target image, was varied.

For a given query image q an image i can be chosen that is either

relatively similar or quite dissimilar to q, using a similarity metric s. If the similarity metric s corresponds to the observers' varying the computed degree of similarity s(q, i) should have an influence on the selection rate. For weak indexing approaches, however, the observed correlation would be low. Therefore, the relationship between the computed similarity s(q, i) and the rate of preferring the image p(q, i) can be used to evaluated the similarity metric s.

6.2 Objectives

Currently, similarity measures were only evaluated for the first best matching images using precision information. But little is known if histogram-based indexing can be used to compare the similarity of relatively distinct images, too. In the experiments we varied the similarity between the target and the query images over a broad range, from best matches to the 2000th image in the result list to test whether the information stored in the indices can predict the similarity judgments of the observers for the different levels of similarity.

The advantage of the 2AFC design over a rating scale is its simplicity. The observers do not need to maintain an internal scale but can directly compare the images. But the disadvantage is that the selection probability p(i) is not only dependent on q but also on the alternative d (distractor). If d for instance is a random image the selection rate should be always greater than 0.5. If d is a quite similar to q than achieving a selection rate greater than 0.5 would be a challenge.

The aim of the first experiment was on the one hand to measure the relationship between preferring one image and the computed similarity over a broad range. On the other hand we wanted to explore how this relationship is modified by varying the similarity of the distractor image. We used the chromaticity histogram for the similarity computation.

In a second experiment the three indices were compared. The indices stored distinct information: the chromaticity histogram encodes the frequency of the color bins, the luminance histograms stores average luminance levels but no frequency information, and both color histograms contain no spatial information. From the Fourier index the bins containing average luminance information were removed so that it only stores the orientation and spatial frequency information. We wanted to known which index would be best suitable for image indexing and to what extend the information sources (chromaticity, luminance, spatial) contributes to the perceived similarity.

In the third experiment the indices' information were combined. We wanted to know if the chromaticity histogram can be improved by using the spatial information and whether the luminance index would further improve, or worsen the concordance with the observers' judgments.

6.3 Method

For all experiments a large commercially database (Corel Corp., 1990) of 60,000 digitized photographs was used. It contains a wide range of themes. Each theme consists of 100 images. The images show, for example, natural and man-made objects, landscapes and close-ups, and were photographed under natural illumination conditions or under artificial lighting.

From the database 900 query images were randomly selected for each experiment. For each of these images the 2000 best matching images for each relevant index or index combination were retrieved. The images with the rank numbers 2, 20, 200 and 2000 were selected for the experiments. In addition, the target image could be a random image. Using the rank numbers rather than the raw distances allows comparing the differently distributed distance functions.

To achieve comparability the distractor was always determined by the color histogram and the intersection metric. With the exception of experiment one where the influence of the distractor similarity was investigated, the rank of the distractor image was always 200. In the first experiment the similarity of distractor images was varied. The similarity rank was 1 (best matches), 200 or random.

The position of the target/distractor (left or right), the order of query images and of the similarity conditions were randomized per subject (mixed design).

The images were displayed on a 21^{°°} computer monitor (Sony GDM-F500) with a resolution of 1280x1024 pixels on a 50% gray background. The experiments were self-paced without decision time limits and lasted between 45 and 60 minutes. For one observer the experiment was stopped after 70 minutes. The 600 comparisons made so far were included in the evaluation. The subjects were undergraduates of psychology who were obliged to participate in experiments for their curriculum and were naive to the intention of the experiments. They were instructed to compare the similarity of the two test images with the image at the top and to decide which image is more similar. Subjects were told that there is no "true or false" and to judge intuitively if unsure. The answers were giving by clicking the left or right mouse button.

6.4 Experiment 1: Influence of distractor similarity

In the first experiment the relationship between the similarity computed with the chromaticity histogram and the human judgments was measured. As a second factor, the similarity of the distractor image was varied to determine how the degree of similarity between the two test images would influence the rate of preferring the target image.

The image similarities were calculated using the chromaticity histogram and the intersection norm. The rank of the distractor image was either 1 (best match), 200, or random. The rank of the target image was 1, 2, 20, 200, 2000, or random. This results in 3×5 conditions because the points of equal target and the distractor ranks were not measured.

The results show a strong correlation between the logarithmic rank of the test image and the probability of preferring (Fig. 9). In figure the similarity rank of the target image is plotted at the x-axis. For each of the three distractor ranks, the rate of preferring the target is shown (y-axis). The (theoretic) points of equal similarity between the target and the distractor image are marked by filled circles. The correlation coefficient between the logarithmic rank and the percentage of concordance is very high (r > .95) and significant (p < .05). Table 1 shows the regression and correlation coefficients.

Distractor Rank	b	a	r
1	022	.49	.985
200	032	.68	.999
Random	027	.80	.965

Table 1: Regression and correlation coefficients for the relationship between logarithmic target rank and concordance for different distractor ranks.

Changing the distractor similarity does not alter the gradient of the linear regression and only shifts the functions by a constant amount. Therefore, the alternative image in the 2AFC design is not a critically value for the evaluation of the indices. For the following exper-

Figure 9: Probability of preferring the target image against the distractor image as a function of similarity between the target and the query image. The similarity distance was calculated using the chromaticity index and the intersection metric. The filled circles indicate hypothetic points of equal similarity of distractor and target image with expected probability .5 and therefore define the rank of the distractor image. The standard error is shown for each condition.

iments we kept the distractor similarity constant. We decided to use the medium distractor similarity (rank 200) optimally using the range of the scale.

6.5 Experiment 2: Index comparison

Color is an important feature of images which contributes to image similarity. But less is known about the importance of the other features such as luminance or contrast information. The experiment 2 addresses the problem by measuring the contribution of the index information to perceived similarity quantitatively.

The image similarity was calculated using the chromaticity histogram, the spatial index and the luminance vector. For the chromaticity histogram the minimum norm was used. The distances between the other vectors were calculated using the Euclidian norm. The distractor image was determined by the chromaticity histogram and had rank 200. The rank of the target image was 1, 2, 20, 2000, or random.

The results show a strong advantage for the chromaticity histogram. For relatively distinct images the luminance and spatial index show comparable performance (rank 20, 2000). But with the luminance index the best matches more similar (rank 1, 2).

Index	b	a	r
Color Frequency	034	.66	.976
Luminance	025	.52	.978
Fourier spectrum	019	.47	.989

Table 2: Regression and correlation coefficients for the relationship between logarithmic target rank and concordance for the different indices.

Figure 10: Relationship between the probability of preferring the target image against the distractor image as a function the similarity between query and target image. The similarity distances were calculated using the chromaticity, luminance and the spatial index. The filled circle indicates the theoretic point where the target and the distractor image are equally similar.

6.6 Experiment 3: Index combination

The performance of the luminance and spatial index is clearly worse than of the chromaticity histogram. Therefore, we wanted to know if the correspondence with the observers' judgments could be improved if the spatial or the spatial and the luminance information are used in addition.

As the similarity function the average of the z-transformed distance values were used. All other parameters correspond to experiment two.

Figure 11 shows a general improvement of the selection rates of the image retrieved when either spatial or spatial and luminance information is combined with the chromaticity histogram. The correspondence with the judgments was improved by 5% if the spatial information is used (Table 3). The luminance information further enhances the concordance by 4%. Therefore, the luminance and the spatial index contribute to image similarity independent of the chromaticity histogram.

The overall improvement of 9% clearly indicates that the z-transformation can be used to combine index information.

Index Combination	b	а	r
Freq.	021	.60	.967
Freq. + Fourier	028	.65	.959
Freq. + Fourier + Lum.	031	.69	.998

Table 3: Regression and correlation coefficients for the relationship between logarithmic target rank and concordance for combinations of the indices.

Figure 11: Relationship between the probability of preferring the target image against the distractor image as a function of the similarity between the query and the target image. The similarity distances were calculated using the chromaticity, the chromaticity and the spatial and all three indices. The filled circle indicates the theoretic point where the target and distractor are equally similar. The standard error is shown for each data point.

7 Discussion

The new approach of our CBIR system was the construction of features in analogy to some of the properties of the early stages of human vision. We used a psychophysical color space and divided it into logarithmical bins reflecting the granularity of higher order color perception. The three information sources chromaticity, luminance and contrasts were stored in separate indices. For the spatial index we used the 2-dimensional DFT to encode the orientation and spatial frequency information of the images. The index predictions of image similarity were directly compared with observers' judgments in a 2AFC design. We found a high correlation between the logarithmic similarity rank and the rate of preferring the image. This correlation was observed for all three indices and for the combination of the index information using the z-transformation. Furthermore, the results show that color histogram indexing could be greatly improved if the spatial and luminance features of images are used in addition.

7.1 Perception Based Image Indexing

Color histograms and their variations are used with great success in many current CBIR systems. The histograms are typically built in RGB or HSI space. For objects that are photographed under different illuminations, color constancy algorithms could improve the retrieval quality (Funt and Finlayson (1995), Gevers and Smeulders (1996), Alferez and Wang (1999)). The spatial information of images was encoded a variety of ways: by multiple histograms (Stricker and Dimai, 1997), correlograms (Huang et al., 1999), explicit texture statistics (Liu and Picard, 1996) and by wavelet transformations (Manjunath and Ma (1996), Wang et al. (1997), Liang and Kuo (1999)).

With the three histograms we tried to use some of the coding principles of the human vision system for the comparison of images. A great variety of image features have already been proposed for CBIR. Most of these features were constructed to optimally represent some, in most cases statistical, properties of images. We created a chromaticity histogram in analogy to processing of color in the human vision system. The color-opponent code in the optical nerve is a nearly optimal representation of color because it removes the correlation between the channels (Buchsbaum and Gottschalk, 1983). But optimal representations for image colors would be better constructed by principal components or cluster analyses. However, in the end the similarity of the images is always judged by human observers. Therefore, using a psychophysical color space should result in a metric which better corresponds to human similarity judgments.

In addition to the frequency encoding chromaticity histogram, we stored the average luminance levels of the color bins for each image in a second vector. The separate processing of chromaticity and luminance (contrast) information is part of various models of visual processing. We here used the separation of chromaticity and luminance information to compare the contribution of both information sources to the similarity judgments. At first, we found that the luminance index is correlated with the observers' judgments, too. The prediction of the perceived similarity is not as good as with the chromaticity histogram. But luminance appears to be considered when images are compared, even if the luminance of the color tones appears not to be as important as their frequency. Illumination invariant indices may therefore only be superior if the database contains many similar objects photographed under various illumination conditions.

The spatial information was extracted using the 2-dimensional DFT. The index was constructed to represent the distribution of orientation and spatial frequency in the image in analogy to the processing of contrast information in the visual cortex. Though many texture feature set describe such information too, the Fourier analysis offers a mathematical profound way to extract the information. The explicit representation of orientation and spatial frequency in the Fourier spectrum allows the simple filtering of these dimensions. In our program the user could for example a radial filter to use the Fourier index as an orientation index only. By averaging the bins of equal frequency ranges rotation invariant search could be conducted.

7.2 Evaluation

Currently, CBIR systems are evaluated by precision and sometimes recall measures. Relevant images are – in the majority of the publication – defined by similar judgments of a single person deciding whether an image belongs to the same category as the query image. The image databases used for evaluation typically contain between hundred and some thousand images.

A very well evaluated system is the PicHunter system (Cox et al. (2000), Papathomas et al. (1998)). The system includes simple features like the image height and width, color histograms, color autocorrelogram, color-coherence vector and – for a subset of the images – semantic annotations. The feature vectors were compared using L_1 norm and the distances are further transformed into probability values using a sigmoidal function. The features were tested in a forced choice design similar to one we used and then later compared within the target testing paradigm (Cox et al., 2000).

But the target testing evaluation procedure used in Papathomas et al. (1998) is limited to relevance feedback systems. It is ideal to evaluate a complete system but it is less ideal to measure the relationship between single features and human perception. With target testing the functional relationship between an index similarity space and the similarity space of human perception could not determined.

Our evaluation scheme coupled with the large image database allows measuring the relationship between the index similarity and the probability of user reaction with high precision. The results suggest that the relationship could be modeled by a logarithmic function between the similarity rank and the selection probability for 2AFC designs. That relationship holds for all indices and is not impacted by the similarity of the distractor image.

For relevance feedback systems measuring the relationship between the similarity metric and the perceived similarity over the whole range of similarity, from the most similar image to random images, is of high importance. Cox et al. (2000) used a sigmoid function to transform the raw distances to a probabilistic scale. We found in the experiments a strong logarithmic relationship between the similarity rank and the probabilistic similarity, for the indices and index combinations. We would suggest that for Bayes relevance feedback systems a linear transformation of the logarithmic rank should be used rather than transformations of the raw distances.
